THE ROLE OF PROTECTIVE GROUPS IN ORGANIC SYNTHESIS

PROPERTIES OF A PROTECTIVE GROUP

When a chemical reaction is to be carried out selectively at one reactive site in a multifunctional compound, other reactive sites must be temporarily blocked. Many protective groups have been, and are being, developed for this purpose. A protective group must fulfill a number of requirements. It must react selectively in good yield to give a protected substrate that is stable to the projected reactions. The protective group must be selectively removed in good yield by readily available, preferably nontoxic reagents that do not attack the regenerated functional group. The protective group should form a derivative (without the generation of new stereogenic centers) that can easily be separated from side products associated with its formation or cleavage. The protective group should have a minimum of additional functionality to avoid further sites of reaction. All things considered, no protective group is the best protective group. Currently, the science and art of organic synthesis, contrary to the opinions of some, has a long way to go before we can call it a finished and well-defined discipline, as is amply illustrated by the extensive use of protective groups during the synthesis of multifunctional molecules. Greater control over the chemistry used in the building of nature’s architecturally beautiful and diverse molecular frameworks, as well as unnatural structures, is needed when one considers the number of protection and deprotection steps often used to synthesize a molecule.

HISTORICAL DEVELOPMENT

Since a few protective groups cannot satisfy all these criteria for elaborate substrates, a large number of mutually complementary protective groups are needed and, indeed, are available. In early syntheses the chemist chose a standard derivative known to be stable to the subsequent reactions. In a synthesis of callistephin chloride the phenolic $\text{-OH}$ group in $\text{1}$ was selectively protected as an acetate.$^1$ In the presence of silver ion the aliphatic hydroxyl group in $\text{2}$ displaced the bromide ion in a bromoglucoside. In a final step the acetate group was removed by basic hydrolysis.

$$\text{NaOH} \quad \text{CH}_3\text{COCl} \quad \text{AcO}$$

Other classical methods of cleavage include acidic hydrolysis (eq. 1), reduction (eq. 2), and oxidation (eq. 3):

1. $\text{ArO} \text{-R} \rightarrow \text{ArOH}$
2. $\text{RO} \text{-CH}_2\text{Ph} \rightarrow \text{ROH}$
3. $\text{RNH} \text{-CHO} \rightarrow [\text{RNHCOOH}] \rightarrow \text{RNH}_3^+$

Some of the original work in the carbohydrate area in particular reveals extensive protection of carbonyl and hydroxyl groups. For example, a cyclic diacetonide of glucose was selectively cleaved to the monoacetonide.$^2$ A summary$^3$ describes the selective protection of primary and secondary hydroxyl groups in a synthesis of gentiobiose, carried out in the 1870s, as triphenylmethyl ethers.

DEVELOPMENT OF NEW PROTECTIVE GROUPS

As chemists proceeded to synthesize more complicated structures, they developed more satisfactory protective groups and more effective methods for the formation and cleavage of protected compounds. At first a tetrahydropyranyl acetal was prepared,$^4$ by an acid-catalyzed reaction with dihydropyran, to protect a hydroxyl group. The acetal is readily cleaved by mild acid hydrolysis, but formation of this acetal introduces a new stereogenic center. Formation of the 4-methoxytetrahydropyranyl ketal$^5$ eliminates this problem.

Catalytic hydrogenolysis of an $O$-benzyl protective group is a mild, selective method introduced by Bergmann and Zervas$^6$ to cleave a benzyl carbamate ($>\text{NCO} \text{-OCH}_2\text{C}_6\text{H}_5 \rightarrow >\text{NH}$) prepared to protect an amino group during peptide syntheses. The method also has been used to cleave alkyl benzyl ethers, stable compounds prepared to protect alkyl alcohols; benzyl esters are cleaved by catalytic hydrogenolysis under neutral conditions.

Three selective methods to remove protective groups have received attention: “assisted,” electrolytic, and photolytic removal. Four examples illustrate “assisted removal” of a protective group. A stable allyl group can be converted to a labile vinyl
ether group (eq. 4); a β-haloethoxy (eq. 5) or a β-silylethoxy (eq. 6) derivative is cleaved by attack at the β-substituent; and a stable o-nitrophenyl derivative can be reduced to the o-amino compound, which undergoes cleavage by nucleophilic displacement (eq. 7):

\[

\end{array}
\end{align*}
\]

R = alkyl, aryl, R’CO−, or R’NHCO−

The design of new protective groups that are cleaved by “assisted removal” is a challenging and rewarding undertaking.

Removal of a protective group by electrolytic oxidation or reduction is useful in some cases. An advantage is that the use and subsequent removal of chemical oxidants or reductants (e.g., Cr or Pb salts; Pt− or Pd−C) are eliminated. Reductive cleavages have been carried out in high yield at −1 to −3 V (vs. SCE), depending on the group; oxidative cleavages in good yield have been realized at 1.5–2 V (vs. SCE). For systems possessing two or more electrochemically labile protective groups, selective cleavage is possible when the half-wave potentials, \( E_{1/2} \), are sufficiently different; excellent selectivity can be obtained with potential differences on the order of 0.25 V. Protective groups that have been removed by electrolytic oxidation or reduction are described at the appropriate places in this book; a review article by Mairanovsky discusses electrochemical removal of protective groups.

Photolytic cleavage reactions (e.g., of o-nitrobenzyl, phenacyl, and nitrophenylsulfenyl derivatives) take place in high yield on irradiation of the protected compound for a few hours at 254–350 nm. For example, the o-nitrobenzyl group, used to protect alcohols, amines, and carboxylic acids, has been removed by irradiation. Protective groups that have been removed by photolysis are described at the appropriate places in this book; in addition, the reader may wish to consult five review articles.

One widely used method involving protected compounds is solid-phase synthesis (polymer-supported reagents). This method has the advantage of simple workup by filtration and automated syntheses, especially of polypeptides, oligonucleotides, and oligosaccharides.

Internal protection, used by van Tamelen in a synthesis of colchicine, may be appropriate:
SELECTION OF A PROTECTIVE GROUP FROM THIS BOOK

To select a specific protective group, the chemist must consider in detail all the reactants, reaction conditions, and functionalities involved in the proposed synthetic scheme. First he or she must evaluate all functional groups in the reactant to determine those that will be unstable to the desired reaction conditions and require protection. The chemist should then examine reactivities of possible protective groups, listed in the Reactivity Charts, to determine compatibility of protective group and reaction conditions. A guide to these considerations is found in Chapter 10. (The protective groups listed in the Reactivity Charts in that chapter were the most widely used groups at the time the charts were prepared in 1979 in a collaborative effort with other members of Professor Corey’s research group.) He or she should consult the complete list of protective groups in the relevant chapter and consider their properties. It will frequently be advisable to examine the use of one protective group for several functional groups (i.e., a 2,2,2-trichloroethyl group to protect a hydroxyl group as an ether, a carboxylic acid as an ester, and an amino group as a carbamate). When several protective groups are to be removed simultaneously, it may be advantageous to use the same protective group to protect different functional groups (e.g., a benzyl group, removed by hydrogenolysis, to protect an alcohol and a carboxylic acid). When selective removal is required, different classes of protection must be used (e.g., a benzyl ether cleaved by hydrogenolysis but stable to basic hydrolysis, to protect an alcohol, and an alkyl ester cleaved by basic hydrolysis but stable to hydrogenolysis, to protect a carboxylic acid). One often overlooked issue in choosing a protective group is that the electronic and steric environments of a given functional group will greatly influence the rates of formation and cleavage. For an obvious example, a tertiary acetate is much more difficult to form or cleave than a primary acetate.

If a satisfactory protective group has not been located, the chemist has a number of alternatives: Rearrange the order of some of the steps in the synthetic scheme so that a functional group no longer requires protection or a protective group that was reactive in the original scheme is now stable; redesign the synthesis, possibly making use of latent functionality (i.e., a functional group in a precursor form; e.g., anisole as a precursor of cyclohexanone). Or, it may be necessary to include the synthesis of a new protective group in the overall plan or better yet, design new chemistry that avoids the use of a protective group.

Several books and chapters are associated with protective group chemistry. Some of these cover the area; others deal with more limited aspects. Protective groups continue to be of great importance in the synthesis of three major classes of naturally
SYNTHESIS OF COMPLEX SUBSTANCES

SYNTHESIS OF COMPLEX SUBSTANCES. TWO EXAMPLES
(AS USED IN THE SYNTHESIS OF HIMASTATIN AND PALYTOXIN)
OF THE SELECTION, INTRODUCTION, AND REMOVAL
OF PROTECTIVE GROUPS

Synthesis of Himastatin

Himastatin, isolated from an actinomycete strain (ATCC) from the Himachal Pradesh State in India and active against gram-positive microorganisms and a variety of tumor probe systems, is a C_{72}H_{104}N_{14}O_{20} compound, 1.\(^{31}\) It has a novel bisindolyl structure in which the two halves of the molecule are identical. Each half contains a cyclic peptidal ester containing an L-tryptophanyl unit, D-threonine, L-leucine, D-[(R)-5-hydroxy]piperazic acid, (S)-2-hydroxyisovaleric acid, and D-valine. Its synthesis\(^{32}\) illustrates several important aspects of protective group usage.

Synthesis of himastatin involved the preparation of the pyrroloindoline moiety A, its conversion to the bisindolyl unit A’\(_2\), synthesis of the peptidal ester moiety B, the subsequent joining of these units (A’\(_2\) and two B units), and cyclization leading to himastatin. The following brief account focuses on the protective group aspects of the synthesis.

Unit A (Scheme 1)

The first objective was the conversion of L-tryptophan into a derivative that could be converted to pyrroloindoline 3, possessing a cis ring fusion and a syn relationship of the carboxyl and hydroxyl groups. This was achieved by the conversions shown in Scheme 1. A critical step was e. Of many variants tried, the use of the trityl group on the NH\(_2\) of tryptophan and the t-buty1 group on the carboxyl resulted in stereospecific oxidative cyclization to afford 3 of the desired cis–syn stereochemistry in good yield.
Bisindolyl Unit A′₂ (Schemes 2 and 3)

The conversion of 3 to 8 is summarized in Scheme 2. The trityl group (too large and too acid-sensitive for the ensuing steps) was removed from N and both N’s were protected by Cbz (benzyloxycarbonyl) groups. Protection of the tertiary OH specifically as the robust TBS (t-butyldimethylsilyl) group was found to be necessary for the sequence involving the electrophilic aromatic substitution step, 5 to 6, and the Stille coupling steps (6 + 7 → 8).

\end{align*}\]
The TBS group then had to be replaced (two steps, Scheme 3: a and b) by the more easily removable TES (triethylsilyl) group to permit deblocking at the last step in the synthesis of himastatin. Before combination of the bisindolyl unit with the peptidal ester unit, several additional changes in the state of protection at the two nitrogens

Scheme 2

The TBS group then had to be replaced (two steps, Scheme 3: a and b) by the more easily removable TES (triethylsilyl) group to permit deblocking at the last step in the synthesis of himastatin. Before combination of the bisindolyl unit with the peptidal ester unit, several additional changes in the state of protection at the two nitrogens
THE ROLE OF PROTECTIVE GROUPS IN ORGANIC SYNTHESIS

and the carboxyl of 8 were needed (Schemes 2 and 3). The Cbz protective groups were removed from both N’s, and the more reactive pyrrolidine N was protected as the FMOC (fluorenylmethoxycarbonyl) group. At the carboxyl, the t-butyl group was replaced by the allyl group. [The smaller allyl group was needed for the later condensation of the adjacent pyrrolidine nitrogen of 15 with the threonine carboxyl of 24 (Scheme 5); also, the allyl group can be cleaved by the Pd(Ph₃P)₄–PhSiH₃ method, conditions under which many protective groups (including, of course, the other protective groups in 25; see Scheme 6) are stable.] Returning to Scheme 3, the FMOC groups on the two equivalent pyrrolidine N’s were then removed, affording 15.

Peptidal Ester Unit B (Schemes 4 and 5)

Several of these steps are common ones in peptide synthesis and involve standard protective groups. Attention is called to the 5-hydroxypiperazic acid. Its synthesis (Scheme 4) has the interesting feature of the introduction of the two nitrogens in protected form as BOC (t-butoxycarbonyl) groups in the same step. Removal of the BOC groups and selective conversion of the nitrogen furthest from the carboxyl group into the N-TeoC (2-trimethylsilyloxy carbonyl) group, followed by hydrolysis of the lactone and TBS protection of the hydroxyl, afforded the piperazic acid entity 16 in a suitable form for combination with dipeptide 18 (Scheme 5). Because of the greater reactivity of the leucyl –NH₂ group of 18 in comparison to the piperazyl –NₐH group in 16, it was not necessary to protect this piperazyl NH in the condensation of 18 and 16 to form 19. In the following step (19 + 20 → 21), this somewhat hindered piperazyl NH is condensed with the acid chloride 20. Note that the hydroxyl in 20 is protected by the FMOC group—not commonly used in

![Scheme 4](image)

(a) TFA (both –NBOC’s → NH)
(b) TeocCl, pyridine (–NH → N-Teoc)
(c) LiOH (lactone → –CO₂⁻ + HO⁻)
(d) TBSOTf, lutidine (–OH → –OTBS)
hydroxyl protection. A requirement for the protective group on this hydroxyl was that it be removable (for the next condensation: 21 + Troc-D-valine 22 → 23) under conditions that would leave unaltered the −COO−allyl, the N-Teoc, and the OTBS groups. The FMOC group (cleavage by piperidine) met this requirement. Choice of the Troc (2,2,2-trichloroethoxycarbonyl) group for N-protection of valine was based on the requirements of removability, without affecting OTBS and OTES groups, and stability to the conditions of removal of allyl from −COO−allyl [easily met by use of Pd(Ph3P)4 for this deblocking].
THE ROLE OF PROTECTIVE GROUPS IN ORGANIC SYNTHESIS

Himastatin 1 (Scheme 6)

Of special importance to the synthesis was the choice of condensing agents and conditions. HATU-HOAt was of particular value in these final stages. Condensation of the threonine carboxyl of 24 (from Scheme 5) with the pyrrolidine N’s of the bisindolyl compound 15 (from Scheme 3) afforded 25. Removal of the allyl groups from the tryptophanyl carboxyls and the Troc groups from the valine amino nitrogens, followed by condensation (macrolactamization), gave 27. Removal of the six silyl groups (the two quite hindered TES groups and the four, more accessible, TBS groups) by fluoride ion afforded himastatin.

Synthesis of Palytoxin Carboxylic Acid

Palytoxin carboxylic acid, C_{123}H_{213}NO_{53}, Figure 1 (R^1–R^8 = H), derived from palytoxin, C_{129}H_{223}N_{3}O_{54}, contains 41 hydroxyl groups, one amino group, one ketal, one hemiketal, and one carboxylic acid, in addition to some double bonds and ether linkages.

The total synthesis was achieved through the synthesis of eight different segments, each requiring extensive use of protective group methodology, followed by the appropriate coupling of the various segments in their protected forms.

The choice of what protective groups to use in the synthesis of each segment was based on three aspects: (a) the specific steps chosen to achieve the synthesis of each
segment; (b) the methods to be used in coupling the various segments, and (c) the conditions needed to deprotect the 42 blocked groups in order to liberate palytoxin carboxylic acid in its unprotected form. (These conditions must be such that the functional groups already deprotected are stable to the successive deblocking conditions.) Kishi’s synthesis employed only eight different protective groups for the 42 functional groups present in the fully protected form of palytoxin carboxylic acid (Figure 1, 1). A few additional protective groups were used for “end group” protection in the synthesis and sequential coupling of the eight different segments. The synthesis was completed by removal of all of the groups by a series of five different methods. The selection, formation, and cleavage of these groups are described below.

For the synthesis of the C.1–C.7 segment, the C.1 carboxylic acid was protected as a methyl ester. The C.5 hydroxyl group was protected as the t-butyldimethylsilyl (TBS) ether. This particular silyl group was chosen because it improved the chemical yield and stereochemistry of the Ni(II)/Cr(II)-mediated coupling reaction of segment C.1–C.7 with segment C.8–C.51. Nine hydroxyl groups were protected as p-methoxyphenylmethyl (MPM) ethers, a group that was stable to the conditions used in the synthesis of the C.8–C.22 segment. These MPM groups were eventually cleaved oxidatively by treatment with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ).

The C.2 hydroxyl group was protected as an acetate, since cleavage of a p-methoxyphenylmethyl (MPM) ether at C.2 proved to be very slow. An acetyl

**Figure 1.** Palytoxin carboxylic acid.
group was also used to protect the C.73 hydroxyl group during synthesis of the right-hand half of the molecule (C.52–C.115). Neither a p-methoxyphenylmethyl (MPM) nor a t-butyldimethylsilyl (TBS) ether was satisfactory at C.73: Dichlorodicyanobenzoquinone (DDQ) cleavage of a p-methoxyphenylmethyl (MPM) ether at C.73 resulted in oxidation of the cis–trans dienol at C.78–C.73 to a cis–trans dienone. When C.73 was protected as a t-butyldimethylsilyl (TBS) ether, Suuzuki coupling of segment C.53–C.75 (in which C.75 was a vinyl iodide) to segment C.76–C.115 was too slow. In the synthesis of segment C.38–C.51, the C.49 hydroxyl group was also protected at one stage as an acetate, to prevent benzoate migration from C.46. The C.8 and C.53 hydroxyl groups were protected as acetates for experimental convenience. A benzoate ester, more electron-withdrawing than an acetate ester, was used to protect the C.46 hydroxyl group to prevent spiroketalization of the C.43 and C.51 hydroxyl groups during synthesis of the C.38–C.51 segment. Benzoate protection of the C.46 hydroxyl group also increased the stability of the C.47 methoxy group (part of a ketal) under acidic cleavage conditions. Benzoates rather than acetates were used during the synthesis of the C.38–C.51 segment since they were more stable and better chromophores in purification and characterization.

Several additional protective groups were used in the coupling of the eight different segments. A tetrahydropyranyl (THP) group was used to protect the hydroxyl group at C.8 in segment C.8–C.22, and a t-butyldiphenylsilyl (TBDPS) group was used for the hydroxyl group at C.37 in segment C.23–C.37. The TBDPS group at C.37 was later removed by Bu₄NOH/THF in the presence of nine p-methoxyphenylmethyl (MPM) groups. After the coupling of segment C.8–C.37 with segment C.38–C.51, the C.8 THP ether was hydrolyzed with pyridinium p-toluenesulfonate (PPTS) in methanol-ether, 42°, in the presence of the bicyclic ketal at C.28–C.33 and the cyclic ketal at C.43–C.47. (As noted above, the resistance of this ketal to these acidic conditions was due to the electron-withdrawing effect of the benzoate at C.46.) A cyclic acetonide (1,3-dioxane) at C.49–C.51 was also removed by this step and had to be reformed (acetone/PPTS) prior to the coupling of segment C.8–C.51 with segment C.1–C.7. After coupling of these segments to form segment C.1–C.51, the new hydroxyl group at C.8 was protected as an acetate, and the acetonide at C.49–C.51 was, again, removed without alteration of the bicyclic ketal at C.28–C.33 or the cyclic ketal at C.43–C.47, still stabilized by the benzoate at C.46.

The synthesis of segment C.77–C.115 from segments C.77–C.84 and C.85–C.115 involved the liberation of an aldehyde at C.85 from its protected form as a dithioacetal, RCH(SEt)₂, by mild oxidative deblocking (I₂/NaHCO₃, acetone, water) and the use of the p-methoxyphenyldiphenylmethyl (MMTr) group to protect the hydroxyl group at C.77. The C.77 MMTr ether was subsequently converted to a primary alcohol (PPTS/MeOH-CH₂Cl₂, rt) without affecting the 19 t-butyldimethylsilyl (TBS) ethers or the cyclic acetonide at C.100–C.101.

The C.100–C.101 diol group, protected as an acetonide, was stable to (a) the Wittig reaction used to form the cis double bond at C.98–C.99 and (b) all of the conditions used in the buildup of segment C.99–C.115 to fully protected palytoxin carboxylic acid (Figure 1, I).
The C.115 amino group was protected as a trimethylsilylethyl carbamate (Me$_3$SiCH$_2$CH$_2$OCONHR), a group that was stable to the synthesis conditions and cleaved by the conditions used to remove the t-butyldimethylsilyl (TBS) ethers.

Thus the 42 functional groups in palytoxin carboxylic acid (39 hydroxyl groups, one diol, one amino group, and one carboxylic acid) were protected by eight different groups:

1 methyl ester  
5 acetate esters  
20 t-butyldimethylsilyl (TBS) ethers  
9 p-methoxyphenylmethyl (MPM) ethers  
4 benzoate esters  
1 methyl “ether”  
1 acetonide  
1 Me$_3$SiCH$_2$CH$_2$OCO

The protective groups were then removed in the following order by the five methods listed below:

1. To cleave p-methoxyphenylmethyl (MPM) ethers: DDQ (dichlorodicyano-benzoquinone)/t-BuOH–CH$_2$Cl$_2$–phosphate buffer (pH 7.0), 4.5 h.
2. To cleave the acetonide: 1.18 N HClO$_4$–THF, 25°C, 8 days.
3. To hydrolyze the acetates and benzoates: 0.08 N LiOH/H$_2$O–MeOH–THF, 25°C, 20 h.
4. To remove t-butyldimethylsilyl (TBS) ethers and the carbamoyl ester (Me$_3$SiCH$_2$CH$_2$OCONHR): Bu$_4$N$^+$/F$^-$, THF, 22°C, 18 h → THF–DMF, 22°C, 72 h.
5. To hydrolyze the methyl ketal at C.47, no longer stabilized by the C.46 benzoate: HOAc–H$_2$O, 22°C, 36 h.

This order was chosen so that DDQ (dichlorodicyano-benzoquinone) treatment would not oxidize a deprotected allylic alcohol at C.73 and so that the C.47 hemiketal would still be protected (as the ketal) during basic hydrolysis (Step 3).

And so the skillful selection, introduction, and removal of a total of 12 different protective groups has played a major role in the successful total synthesis of palytoxin carboxylic acid (Figure 1, 2).

2. E. Fischer, Ber., 28, 1145 (1895); see p. 1165.

34. HOAt, 7-aza-1-hydroxybenzotriazole; HATU (CAS Registry No. 148893-10-1), N-[(dimethylamino)(3H-1,2,3-triazolo(4,5-b)pyridin-3-yl)oxy]methylene]-N-methylmethanaminium hexafluorophosphate, previously known as O-(7-azabenzotriazol-1-N-oxide)N-methyl-N-methylmethanaminium hexafluorophosphate. [Note Assignment of structure to HATU as a guanidinium species rather than as a uronium species—that is, attachment of the (Me2N)3/H11005 unit to N3 of 7-azabenzotriazole 1-N-oxide instead of to the O—is based on X-ray analysis (ref. 33b).]
